G. Lafayette Maynard /

Date approved by Chairman: Aug 15 1975

## ACKNOWLEDGMENTS

The author wishes to express his appreciation to Dr. L. Timothy Long for his useful suggestions and his support in this study. Thanks are expressed to Drs. G. Lafayette Maynard and Robert Lowell for reviewing this manuscript. The author would also like to thank Dr. Al Erickson of the University of Georgia and Peter Popenoe of the United States Geological Survey for the loan of their gravimeters for this study.

Support, in part, was received by the author during his tenure as a graduate student through research assistantships made possible by an U.S. Geological Survey Grant #14-08-0001-G-127 and an Army Research Office Grant #DAHCO4-74-G-0003. The research for this thesis was supported by the U.S. Geological Survey grant. The author wishes to thank the sponsors of this grant.

Special thanks are due to James Butler, Rick Garfield, and David Hopkins who participated in the collection of the data for this study. Special thanks also go to my wife, Karen, for her patience and assistance in the collection of the data, as well as the editing of this manuscript.

## SUMMARY

Approximately 2000 new gravity measurements were made near Charleston, South Carolina, in the suspected epicentral zone of the 1886 earthquake. These data were used to construct a simple Bouguer gravity map. The data were contoured at 1 milligal intervals. The contours delineate several major features. In the central western quadrangle, a large positive anomaly exhibits a steep gravity gradient of 2 to 3 milligals per kilometer on both its northern and southern sides. This positive anomaly is interpreted to result from a large basic plug which extends upward to within 1 kilometer of the surface. To the east of this anomaly the gradient becomes less steep and the contours begin to spread, forming a nose-like, low-magnitude, positive anomaly. This anomaly is considered to result from basic flows intermixed with coastal plain sediments. Surrounding the nose-like anomaly there are large negative anomalies which are interpreted to be representative of deep sedimentary basins. The northern quadrangles contain several low-magnitude positive and negative anomalies which are interpreted to represent, respectively, small basic plugs and shallow basins. The map also suggests the presence of a linear anomaly which trends approximately N 45° E and passes 6 kilometers to the southeast of Summerville, South Carolina. This linear anomaly is observed in a residual Bouguer gravity anomaly map as well as in a two-dimensional spectral analysis of the residual gravity.

Three-dimensional modeling of the simple Bouguer gravity data

shows that the linear alignment of anomalies can be interpreted to result from basic flows which are down-faulted to the southeast. The throw on the interpreted fault would be on the order of 1.5 kilometers. The magnitude of this throw agrees with that determined by two-dimensional modeling of a pair of detailed gravity profiles which traverse this lineation.

Cross correlation coefficients between gravity and topography were computed for each of eleven detailed gravity profiles and their residuals. Four of the five traverses crossing the linear anomaly show close correspondence between gravity and topography. This may indicate that structural features in the basement rocks are paralleled by the surface topography. Similarly, close correspondence between two residual gravity profiles and topography may indicate that these basement structures locally extend into the sedimentary beds above the basement, which in turn, may be indicative of recent vertical movement.

Based on five detailed gravity profiles, the northeastern termination of this linear anomaly, which is interpreted as a fault, is just north of the northeastern sedimentary basin observed on the simple Bouguer gravity map. The southwestern extent of this feature is uncertain, but it is not considered to terminate within the area of investigation.

In general, it is not unreasonable to expect that such a fault exists under the Atlantic Coastal Plain because many such buried grabens have been found. However, it is suggested that well loggings should be concentrated within this area to determine the validity of this interpretation. If a graben is present, isostatic readjustments within such a down-faulted block may explain the earthquake activity in this area.

## CHAPTER I

### INTRODUCTION

Within recorded history, several damaging earthquakes have occurred in the area of Charleston, South Carolina. The most disastrous of these was the August 31, 1886, earthquake which resulted in the loss of several lives and considerable damage to various structures in the city of Charleston and the surrounding area.

Although many events have been felt in the region since 1886, no fault to which the activity can be definitely attributed has been located, nor has any other satisfactory cause for the seismicity been determined. The probable reason that no tectonic cause has yet been agreed upon is that the structure responsible is not only apparently quite complex, but also is hidden by approximately 2500 feet of Post Paleozoic sediments and basalts. The surface of these sediments shows no evidence of displacements related to the earthquakes. Woollard, et al., (1957) were among the first to approach the problem of the structure of the Coastal Plain basement rocks through geophysical methods. They obtained regional gravity data at an average station spacing of 5 kilometers and ran seismic refraction profiles in most of the eastern states adjoining the Atlantic Ocean. However, they obtained very little data in the Charleston-Summerville area. The lack of detailed regional data prevented detailed structural analysis of the crystalline basement in this area.

Cooke (1936) after logging a deep well near Summerville, South

Carolina, reported that the well bottomed in basalts after passing through an 800-foot layer of Triassic sediments. This report led many to believe that there might be a relationship between the Florence Triassic basin and the Charleston area.

Mansfield (1936) also studied these well cuttings. He reported that the cuttings contained no Triassic sediments and dated the material which Cooke had called Triassic as Cretaceous. Woollard, et al., (1957), assuming that Mansfield was correct, suggested that the epicentral area near Charleston, South Carolina, might be related to some structure other than the Florence basin, and suggested the Yamacraw Ridge and the associated basement valley to the north of it.

Pooley (1960) studied the Yamacraw uplift in detail (Figure 1). He concluded that his seismic information did not preclude the possibility that the earthquakes to the north of this ridge resulted from faulting and folding due to this uplift.

Sheridan (1974) suggested that extensive block faulting has controlled the shape and location of major marginal basins. Wrench fault motion within these basins may have produced tensional faults along hingements. Sheridan also suggested that this faulting would be compatible with the rifting of the North American and Afro-European plates during the Jurassic. Associated with such tensional faulting of the continental margins, lithospheric density changes may have caused drastic subsidence.

Long (1975) has suggested that the earthquake activity in the South Carolina Coastal Plain may result from crustal flexing in response to isostatic readjustments of neighboring crustal rock having different

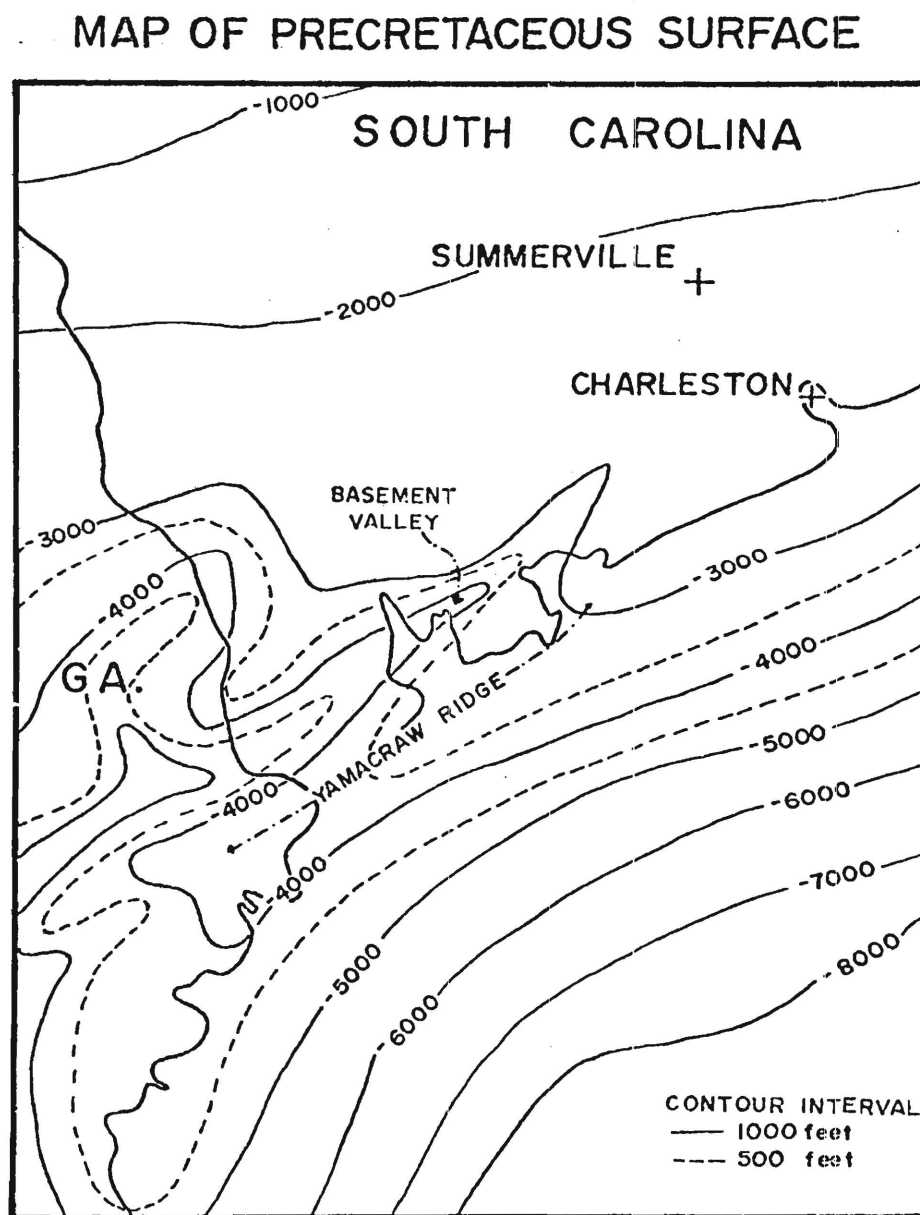

Figure 1. Map of Precretaceous Surface (after Pooley, 1960).

elastic characteristics. Under this assumption, earthquakes should be associated with more rigid rock such as basalts and diabases. Such rocks have been identified in the Charleston-Summerville area.

The purpose of this study was to obtain detailed gravity data in the Charleston epicentral region to be used to construct a structural model of this region which might aid in the search for a geologic cause of the region's tectonic activity.

## CHAPTER II

### GEOLOGIC SETTING

The stratigraphy determined for the Charleston-Summerville, South Carolina, region is based primarily on two well logs. A deep well near Summerville (Figure 2) passed through 2500 feet of Post Paleozoic sediments before reaching basalts at the bottom of the well. Cooke (1936) interpreted this well log. He identified the top 40 feet of sediments as Duplin Marl, which is a white sandy marl, and possibly the Hawthorn Formation, which consists of a gray clay, medium to fine grained sand, and a hard "shell rock". The Duplin Marl and the Hawthorn Formation are Miocene sediments. The Eocene beds, Cooper Marl, and Santee Limestone, lie below the Miocene beds and extend to a depth of approximately 300 feet. The Cooper Marl is a granular marl containing Foraminifera fossils. Santee Limestone is a soft cream-colored limestone. The Peedee Formation and possibly the Black Creek, or Tuscaloosa Formation, were logged between the depths of 300 feet and 1500 feet. This Upper Cretaceous material consists of dark gray, gritty clay and marl containing *Inoceramus* and *Beleminitella* fossils. Positive identification of the Tuscaloosa Formation was not possible, but was considered to comprise the region between 700 feet and 1580 feet. The material between 700 feet and 1500 feet contains a coarse quartz sand and a gray, rusty sand. Any fossil fragments found in the well cuttings from this depth were considered to be derived from fossiliferous beds above the 700 foot depth. At depths below 1580 feet, Cooke (1936) found material

consisting of a reddish sandstone and shale, intermixed with diabase which he interpreted to be Triassic. These Triassic sediments were thought to be of the Newark group. Crystalline basement, consisting of basalt, was encountered at 2550 feet, the bottom of the well. If Cooke's interpretation is correct, the region around Summerville, South Carolina, may have been a hill during the Triassic upon which no Tuscaloosa sediments were deposited.

Mansfield (1936) reinterpreted the well log near Summerville. Using paleontological data, he reported the region below 1600 feet to contain the Upper Cretaceous Tuscaloosa Formation. This region contained reddish sandy clay with inclusions of coarse quartz grains which, according to Stephenson (1926), suggests a delta or terrestrial deposit rather than a Triassic or deep water sedimentation. Mansfield states that the basement basalt is of an undetermined age.

Woollard, et al., (1957) gives a brief account of a 2000-foot well at Charleston, South Carolina, which was initially logged by Stephenson (1926). The strata encountered between the depths of 450 and 750 feet yielded no discernible fossils, but the area was thought to be Upper Cretaceous or Eocene. Foraminifera fossils which are considered characteristic of Cretaceous rock were found at 750 feet. Neither crystalline basement rock nor the Tuscaloosa Formation were reached.

Woollard, et al., (1957) used the formation from these two wells and his seismic refraction data to extrapolate a crystalline basement slope between Summerville and Charleston, South Carolina, of approximately  $1^{\circ}$ . However, Woollard's data were too general to be used to

determine detailed structural trends in the Charleston-Summerville area.

# DEEP WELL NEAR SUMMERVILLE, S.C. LOGGED BY COOKE

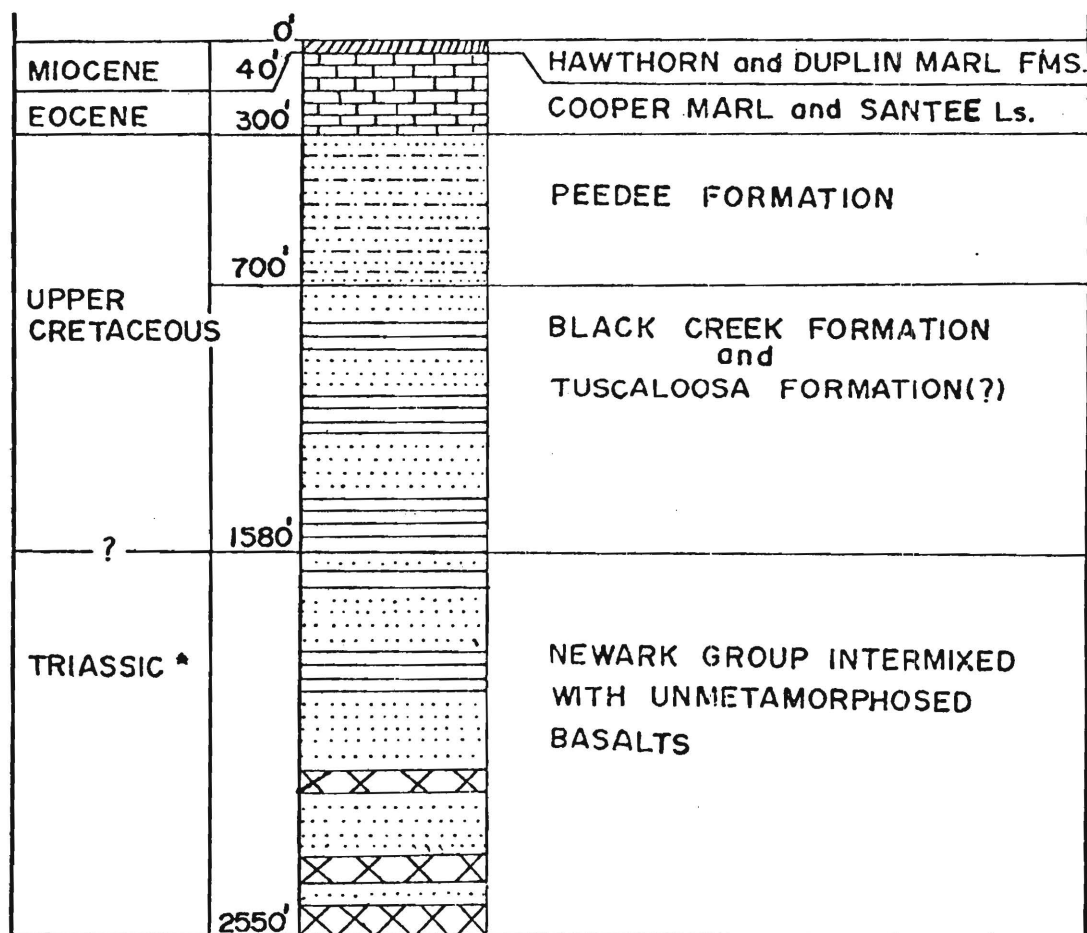

Figure 2. Deep Well Near Summerville, South Carolina (after Cooke, 1936). (\*Mansfield (1936) disputed Cooke's interpretation of the material between the depths of 1580' and 2550'. He dated this rock as Cretaceous.)

### CHAPTER III

#### REGIONAL GRAVITY

Based on gravity measurements made at approximately 2000 locations in the Charleston-Summerville, South Carolina, region (Figure 3) a simple Bouguer gravity map was constructed (Figure 4). The borders of the area investigated are defined by the corner locations N  $32^{\circ} 37.5'$ , W  $80^{\circ} 00'$ ; and N  $33^{\circ} 7.5'$ , W  $80^{\circ} 22.5'$ . The area includes a major portion of the suspected epicentral zone of the 1886 earthquake as well as the epicenters of more recent seismic events such as the November 22, 1974, earthquake. The maximum estimated error in the gravity data is 0.20 milligal (Appendix I). The data were contoured at 1 milligal intervals.

There are several major features delineated by the isogals. In the central western quadrangles, a positive anomaly having a peak value of 15 milligals exhibits a steep gravity gradient of 2 to 3 milligals per kilometer on both its northern and southern sides. To the east of this feature, the gravity gradient becomes less steep, and the isogals spread to form a nose-like feature. To the south and to the northeast, negative anomalies appear to form an arc about the nose-like feature. The northwestern quadrangles are characterized by a reasonably constant negative gravity anomaly field of approximately -3 milligals. Dispersed throughout this region, small zones of slightly more positive and negative anomalies are observed.

Three prominent zones of alignment of contour lines and anomalies can be observed. The trend of the strongest alignment of gravity

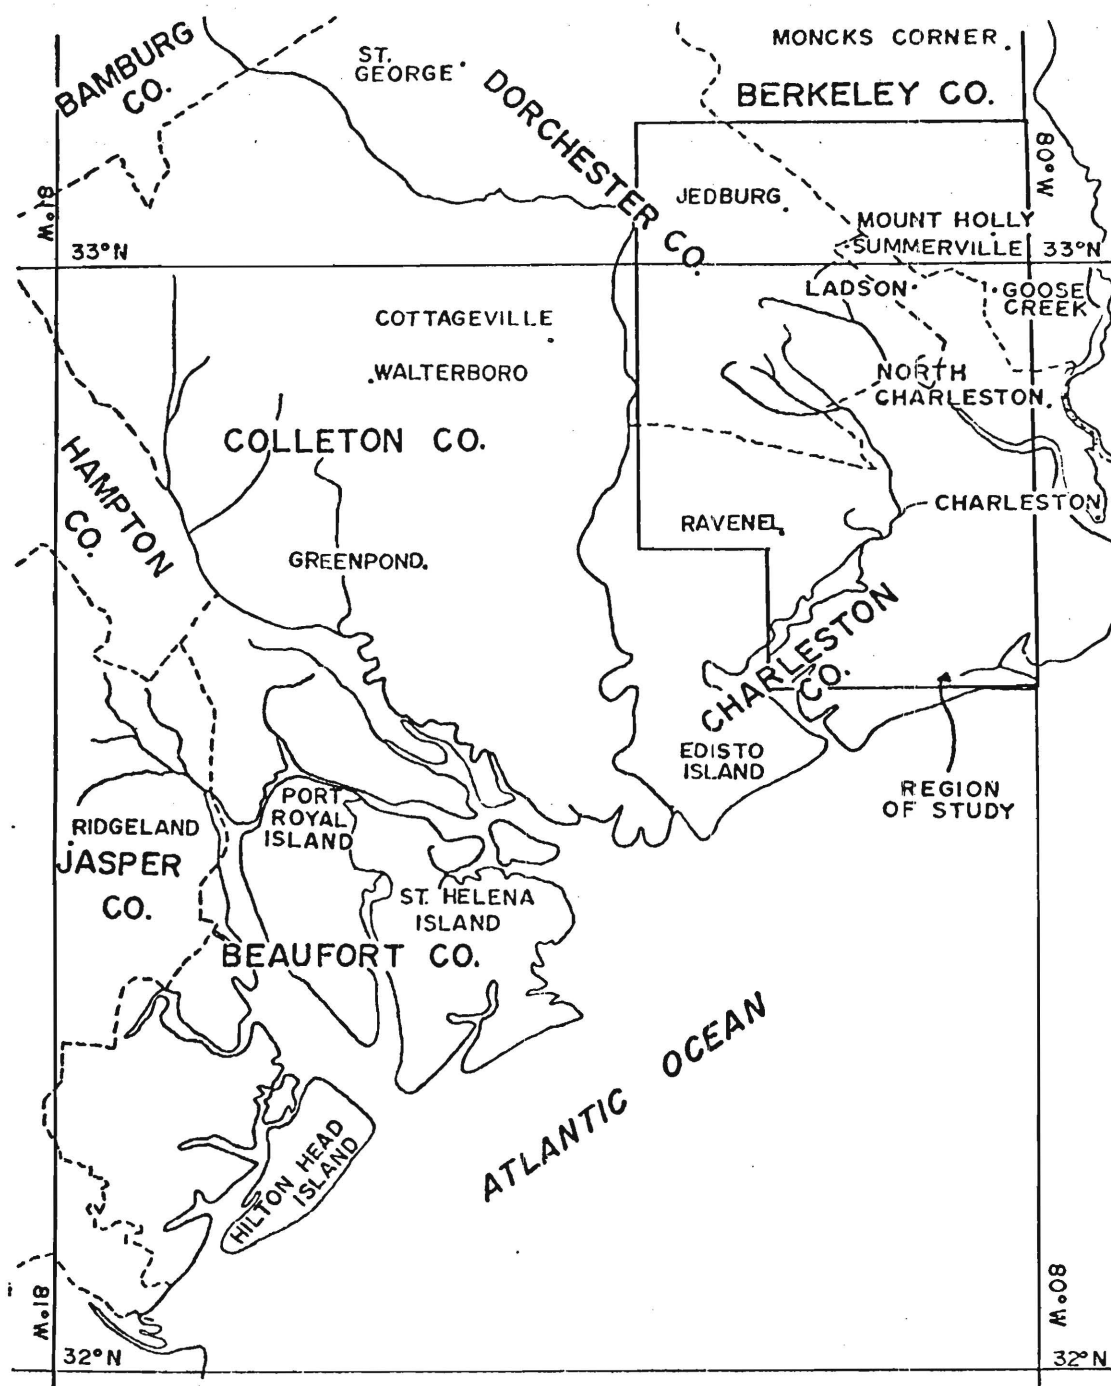

Figure 3. Index Map Showing the Location of the Region of Study (portion of State of South Carolina Map published by U.S.G.S., 1970).

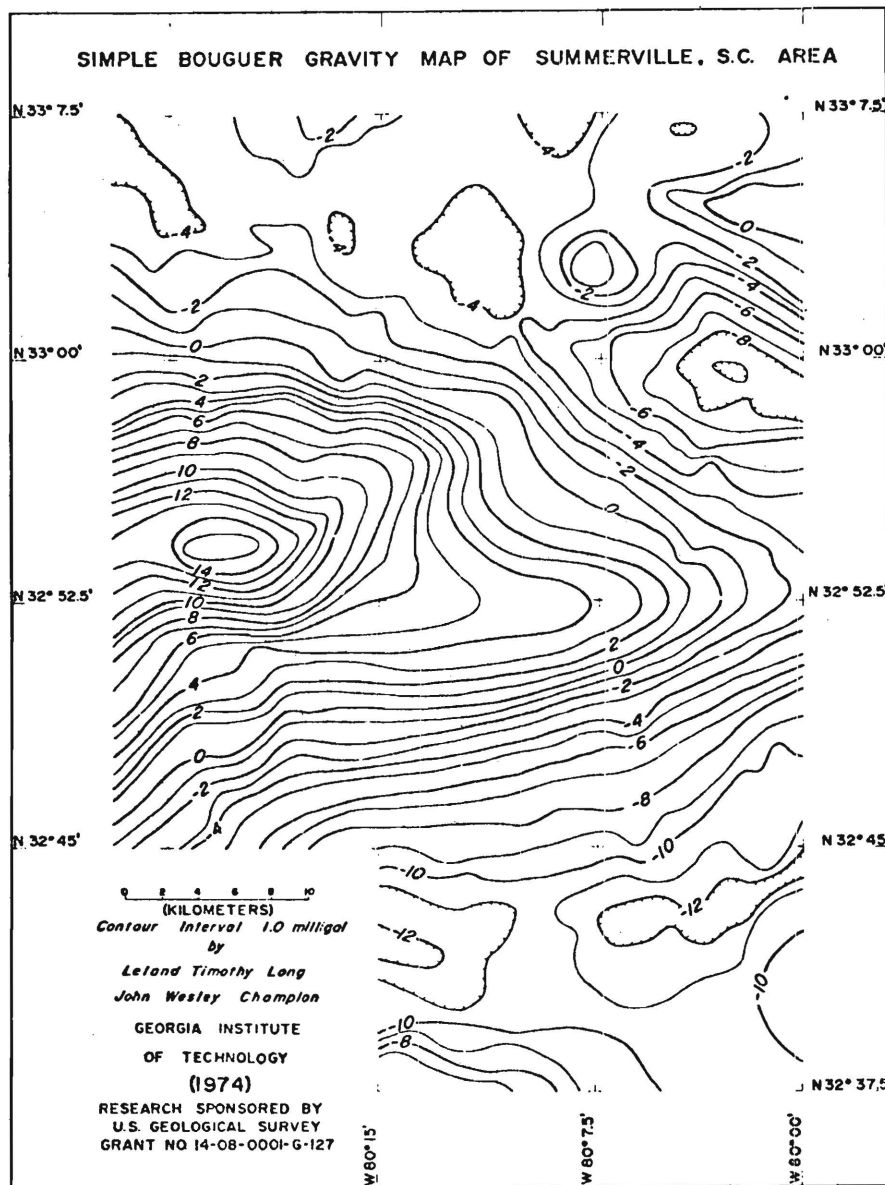

Figure 4. Simple Bouguer Gravity Map of Summerville, South Carolina, Area. (It is contoured at 1 milligal intervals.)

contours is approximately east-west and is formed by isogals south of the central positives. Another alignment of contours is defined by the trend of the isogals north of the central positives and bears approximately N 50° W. These two contour alignments appear to be a consequence of the shape of the central positive anomalies. A third alignment is defined by the western termination of the northeastern and southern negative anomalies. The northwestern edges of these negative regions defines an alignment of anomalies trending N 40° to 50° E which intersects the central positive anomalies in the region where the isogals begin to spread to form the nose-like positive anomaly.

## CHAPTER IV

## ANALYSIS OF GRIDDED GRAVITY DATA

Residual Gravity Anomalies

The gravity data were gridded at 1 kilometer intervals encompassing the area defined by the simple Bouguer gravity map. A regional gravity grid was determined from the gridded gravity data by a two-dimensional smoothing operator devised by Shapiro (1970). It consists of the application of a one-dimensional smoothing operator to the entire data set, first in one direction and then in the other direction. The one-dimensional operator in the  $i$ th direction has the form:

$$Z_{ij}^i = Z_{ij} + S/2(Z_{i-1,j} + Z_{i+1,j} - 2Z_{ij})$$

$Z_{ij}^i$  = Smoothed value of the  $i,j$  grid point in the  $i$ th direction

$Z_{ij}$  = Unsmoothed  $i,j$  grid point

$S$  = Damping constant (usually 0.5 or -0.5)

$Z(x,y)$  is considered to be composed of the sum of two-dimensional Fourier components of the form:

$$Z_{ij} = C + A \cos k(x_i - \phi) \cos (h(y_i - \theta))$$

$k$  = wave number in  $x$  direction

$h$  = wave number in  $y$  direction

$\phi$  = phase displacement in  $x$  direction

$\theta$  = phase displacement in y direction

A = spectral amplitude

The ratio of the smoothed to unsmoothed spectral amplitudes,  $R(k,h)$ , is defined as the two-dimensional response function of the smoothing operator.

$$R(k,h) = [1 - S(1 - \cos k\Delta x)][1 - S(1 - \cos(h\Delta y))]$$

$\Delta x \rightarrow$  grid interval in x direction

$\Delta y \rightarrow$  grid interval in y direction

When S is +0.5 the smoothing operator has the property of damping short wavelengths (high frequencies) in a function. If the operator is applied "n" times, each operation decreases the prominence of the short wavelengths in proportion to the nth power of the response function.

Regional anomalies are determined by using the smoothing operator six times in succession on the two-dimensional gridded gravity data. The regional field is then subtracted from the original gravity grid and the difference is defined to be the residual anomalies. The residual anomalies are the short wavelength anomalies which are removed by the smoothing operator from the original gravity field. Since the width of the smoothing operator is 5.0 kilometers, they are considered to be representative of crustal features having depths less than 2.5 kilometers. Figure 5 is the residual gravity map which is contoured at a 0.5 milligal interval. Positive anomalies appear in the central quadrangles as observed in the original data set. This implies that a portion of the source of these anomalies is less than 2.5 kilometers

Figure 5. Residual Gravity Map of the Summerville, South Carolina, Area. (The map shows the N.E. trending, low-magnitude, negative anomaly separating the two peaks of the central western positive anomaly from the broad eastern central positive anomaly.) (The area outlined by the dashed line is the 32 kilometer square region which is spectral analyzed for lineations.)

deep. The westernmost positive exhibits two peaks, and the eastern nose-like anomaly exhibits only one small peak surrounded by a large low-magnitude positive region. A negative zone trending N 45° E separates the two peaks of the westernmost positive from the nose-like positive. The negative zone corresponds in location and trend with the western terminations of the northeastern and southern Bouguer negative anomalies. Another trend is delineated by the north and south edges of the centrally located positive anomalies. This alignment of isogals trends east-west. Another trend is evident in the northeastern quadrangle. It is defined by a low magnitude negative anomaly zone which separates two large positive residual gravity anomalies. The trend of this lineation is approximately N 35° W.

#### Spectral Analysis of Lineations

In order to determine the limits of resolution where lineations observed in the residual gravity grid are concerned, a 32 kilometer square area (Figure 6) was spectrally analyzed using a two-dimensional Fast Fourier Transformation. Such an analysis allows one to find those wave numbers which are common throughout the function, since these form zones of high magnitude in the transformed domain. Lineations observed in gravity contours are represented in the wave number domain as wave numbers oriented perpendicular to the orientation of the isogals. Therefore, the spectrum must be rotated 90° to coincide with the lineations of the real domain (Figure 7). The area of interest is defined by a shell which has an inner radius of  $(4 \text{ km})^{-1}$ . The  $(4 \text{ km})^{-1}$  radius circle contains the wave numbers of gravity wavelengths greater than 4 kilometers which are not removed in computing the residual. Low

Figure 6. Complex Modulus of the Fourier Spectrum of the 32 Kilometer Square Region Outlined in the Residual Gravity Map.

Figure 7. Diagrams Showing the Rotation of Real Lineations in the Fourier Spectrum Domain.

frequency components of gravity anomalies which are truncated at the borders of the 32 kilometer square area are also observed within the circle.

Within the shell several weak lineations are apparent. The strongest of these trends is directed almost east-west. The orientation of this trend is parallel to the direction of the apparent alignment of the central positive residual anomalies. A second trend is directed approximately N 45° E. This trend parallels the northeastern alignment of negative anomalies observed in the residual gravity. This lineation is also observed in the simple Bouguer gravity map to be the trend defined by the western termination of the northeastern and southern negative anomalies. Another lineation bears approximately north-south and is the result of the truncation of positive anomalies on the eastern and western borders of the area. Lastly, a high frequency trend bearing northwest is not easily recognized in the residual gravity map. The trend may be the result of an alignment of low amplitude short wavelength anomalies in that direction.

#### Three-Dimensional Theoretical Gravity Modeling

Grant, et al., (1965) have suggested that two-dimensional gravity modeling has many drawbacks such as the inherent inability to handle the effects of regional trends or the effects of truncation of two-dimensional structures. Three-dimensional modeling, on the other hand, has the ability to reproduce regional gravity fields as well as to determine nonunique three-dimensional structural solutions. For this reason, three-dimensional modeling was chosen as the indirect method to be used to determine a geologically acceptable crustal structure for the

Summerville-Charleston, South Carolina, area.

Talwani, et al., (1960) showed that gravity anomalies produced by three-dimensional bodies of arbitrary shape could be calculated by approximating the irregularly shaped bodies by several stacked horizontal polygons of constant thickness. The thickness of each polygon is controlled by the effective density contrast. Each polygon's thickness is kept small with respect to its depth. The method of Talwani, et al. was used to construct the following crustal models for the Summerville-Charleston, South Carolina, area.

The region modeled was chosen to be larger than the area defined by the Summerville simple Bouguer gravity map, to allow for accurate modeling of anomalies that terminate at the western edge of the map. The region selected for modeling has its origin at the upper north-eastern corner of the Summerville map and extends 75 kilometers west of this point and 55 kilometers to the south. The data used for preliminary modeling were selected from Woollard's regional gravity data and were gridded at 5 kilometer intervals. The 1 kilometer gridded data in the Summerville area were used to improve the details of the preliminary model. Models No. 1 and No. 2 included the entire area modeled, but only the region encompassed by the Summerville map was revised by the utilization of data from the kilometer grid. The densities used for the anomalous masses were chosen to agree with the density contrasts used in modeling, with  $2.67\text{gm/cm}^3$  used as the reference density (Figures 8 and 9).

#### Model No. 1

Under the assumption that the gravity anomalies in the

Summerville area are produced by shallow crustal bodies, a three-dimensional model was constructed. This model consists of three horizontal, 2 kilometer thick layers which lie between the depths of 2.5 and 8.5 kilometers. The Coastal Plain sediments occupying the upper 2.5 kilometers of the crust are not considered to contribute to the observed gravity anomalies. The top layer, which lies between the depths of 2.5 to 4.5 kilometers, consists of two central western  $2.9 \text{ gm/cm}^3$  bodies intruding a less dense  $2.8 \text{ gm/cm}^3$  irregularly shaped material. This  $2.89 \text{ gm/cm}^3$  material is surrounded on all sides by  $2.67 \text{ gm/cm}^3$  country rock. The eastern termination of this material lies along a lineation which trends  $N 30^\circ E$ . This lineation corresponds generally in direction and location to the northeastern linear anomaly observed in the simple Bouguer gravity map and the residual gravity map.

The second layer, (4.5 to 6.5 kilometers), consists of two regions having densities of  $2.8 \text{ gm/cm}^3$  and three lower density  $2.4 \text{ gm/cm}^3$  regions. The  $2.8 \text{ gm/cm}^3$  region of the first layer is continuous in this layer with a similar "nose-like" feature extending to the east. The nose-like anomalous body is partially surrounded by low density  $2.4 \text{ gm/cm}^3$  features to the northeast and southeast. The western edge of this feature coincides with the previously discussed northeastern lineation. The westernmost extent of the northeastern and southern low density zones also coincides with this lineation.

The third layer, (4.5 to 6.5 kilometers), contains only a  $2.8 \text{ gm/cm}^3$  "nose-like" feature. The western termination of this feature strikes approximately  $N 50^\circ E$ . Again, this correlates with the

northeastern lineation observed in the other analyses.

#### Model No. 2

Under the assumption that the large positive gravity anomaly observed in the western central quadrant of the Summerville map originates at a crustal depth of 16.5 kilometers and extends upward to within 2.5 kilometers of the surface, a second three-dimensional, four layer model was constructed. The top layer, which lies between the depths of 2.5 and 3.5 kilometers, consists of two centrally located  $3.0 \text{ gm/cm}^3$  bodies intruding a lower density,  $2.4 \text{ gm/cm}^3$ , region. No feature in this layer corresponds to the  $2.8 \text{ gm/cm}^3$  structure found in the first layer of Model No. 1. The second layer, (3.5 to 4.5 kilometers), contains three  $3.0 \text{ gm/cm}^3$  bodies. The westernmost centrally located body corresponds to the westernmost  $3.0 \text{ gm/cm}^3$  feature of the first layer. To the east of this feature, another  $3.0 \text{ gm/cm}^3$  body lies beneath the easternmost centrally located high density body of the first layer. A third  $3.0 \text{ gm/cm}^3$  nose-like feature extends to the east of this body. To the northeast and south of the nose-like feature lie lower density  $2.4 \text{ gm/cm}^3$  regions. The western edge of the nose-like feature forms a lineation which includes the westernmost extent of the northeastern and southern low density zones. The trend of this lineation is  $N 45^\circ E$ . The third layer, (4.5 to 7.5 kilometers), contains the two centrally located  $3.0 \text{ gm/cm}^3$  bodies which continue downward to a depth of 7.5 kilometers. The low density zones of the second layer and the nose-like  $3.0 \text{ gm/cm}^3$  feature continue to this depth, also. However, the northeastern section of the easternmost centrally located  $3.0 \text{ gm/cm}^3$  body terminates at a depth of 6.5 kilometers. The western edge

of the nose-like appendage forms a lineation which trends N 45° E. The fourth layer shows the downward continuation of both centrally located positives to a depth of 16.5 kilometers.

Both models suggest the presence of a vertical offset of the nose-like appendage with respect to the eastern central high density bodies. In both models, the offset appears to be associated with the northeast lineation. In the first model, the nose-like appendage of  $2.8 \text{ gm/cm}^3$  density is observed only in the second and third layers, and thus appears to be unconformably offset 2 kilometers downward from the first layer. The second model shows the nose-like feature to be present in the 3.5 to 4.5 kilometer layer. This feature extends downward to a depth of 7.5 kilometers, while the northeastern edge of the eastern central positive extends to a depth of only 6.0 kilometers. This observation, as well as the fact that the nose-like feature is not modeled in the top layer, may indicate an unconformable offset in the model of 1 to 1.5 kilometers.

The two preceding three-dimensional models produced gravity anomalies which agreed to within 10% with the gridded Summerville gravity data. Other models, which did not contain a vertical offset were constructed, but the effective density contrasts required for these models were not realistic.

Figure 8. Three-Dimensional Model No. 1. (The model consists of three, 2 kilometer thick layers which give evidence for vertical offset of the nose-like feature along a N.E. lineation.)

Figure 9. Three-Dimensional Model No. 2. (This model also suggests a vertical offset of the nose-like feature along a N.E. lineation.)

## CHAPTER V

### DETAILED GRAVITY PROFILES AND TWO-DIMENSIONAL GRAVITY ANALYSIS

#### Two-Dimensional Theoretical Models

Theoretical anomalies are calculated for "step model" faults for comparison with observed anomalies. The method of Talwani, et al., (1959) is used to compute the anomalies resulting from faults at depths of 0.5, 1.0, and 2.0 kilometers which vary in throw from 1, 2, or 3 kilometers. These depths are based on estimates by Cooke (1936) and Mansfield (1936) for the depth to the crystalline basement. As would be expected, the anomalies resulting from the fault models are asymmetric about the edge of the fault. As depth to fault increases, the sigmoidal anomaly becomes extended, producing lower gradients. Increasing the throw on the fault has a similar effect, but it primarily determines the radii of curvature in the profile on either side of the fault location. In general, the wavelength of the anomaly increases with both depth to the fault and throw of the fault. Since the shapes of the anomalies are determined by structural shape and not density, the theoretical curves were normalized and compared to normalized observed profiles (Figures 10, 11, and 12). However, once the depths are determined, the density can be computed.

#### Cross Correlation Coefficients

In order to determine and quantify any relationship between

Figure 10. Normalized Curves for a "Step" Fault at 0.5 Kilometers Showing the Effects of Fault Offsets of 1.0, 2.0, and 3.0 Kilometer on the Shape of the Vertical Gravity Anomaly.

Figure 11. Normalized Curves for a "Step" Fault at 1.0 Kilometer Showing the Effects of Fault Offsets of 1.0, 2.0, and 3.0 Kilometers on the Shape of the Vertical Gravity Anomaly.

Figure 12. Normalized Curves for a "Step" Fault at 2.0 Kilometers Showing the Effects of Fault Offsets of 1.0 and 2.0 Kilometers on the Shape of the Vertical Gravity Anomaly.

observed gravity and topography along detailed profiles, cross correlation coefficients between elevation and gravity are computed for each profile. The coefficients are calculated using the method described by Pick, et al., (1973). One usually attempts to pick a reduction density which removes all the topographic masses. However, in the Summerville area, the necessary reduction densities to remove correlation between the topography and gravity are unrealistic.

There are advantages, however, to having a correlation between elevation and gravity. This relationship can add information concerning the control of surface topography by basement structure. For example, a strong positive correlation in a region where faulting is suspected may show the response of the surface to faulting. On the other hand, a negative correlation may result from inaccurate determination of station elevation in an area, or the structural control of a river which channels a region showing a large positive gravity gradient.

In general, correlation coefficients in the following detailed gravity profiles are used to see if topographic features might indicate the presence of faulting along the northeast lineation. Both residual profiles and observed gravity are compared with elevation (Table 1).

#### Detailed Gravity Profiles

Eleven detailed gravity profiles have been established utilizing most of the major highways in the area of investigation (Figure 13). Along each profile, the average station spacing is 0.3 kilometers. Five of the profiles traverse the northeast-trending linear anomaly. Residual profiles were obtained by subtracting the regional profile from the observed gravity profile. In this instance, the regional

KK'	.29	.12

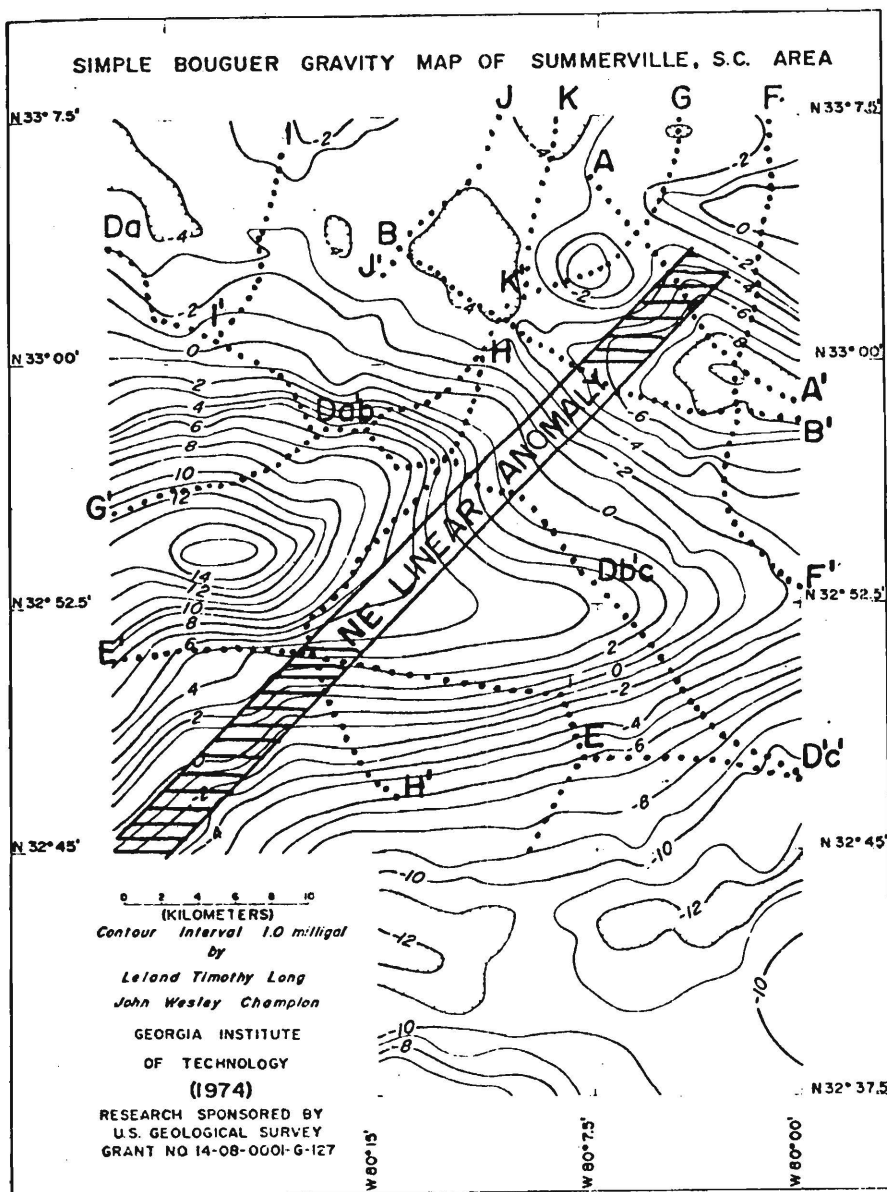

Figure 13. Index Map Showing the Locations of Each of the Detailed Gravity Profiles with Respect to the N.E. Linear Anomaly.

profile was determined from a four-times smoothed, 1 kilometer interval grid. Each regional line point was calculated by determining a curved surface which best fit the nine nearest regional grid points. The contribution of each grid point was determined with respect to distance from the line point and the effects of all nine points were totaled to give the regional point value. The residual profiles are considered to result from the effects of bodies lying at depths no greater than 1 kilometer. Descriptions of the locations for the eleven profiles are given in Appendix I (Table 2).

#### Profile AA'

Profile AA' exhibits negative anomalies which indicate the existence of low density material in this region. At approximately 5.5 kilometers from the eastern end of the profile, a steep negative gravity gradient of -0.8 milligal per kilometer is observed. The location of this gradient is coincident with the northeastern lineation seen in the two-dimensional residual data set (Figure 14).

Examination of the theoretical anomaly curves for idealized faults suggests that the anomaly is produced by a fault having its up side at a depth of 1 kilometer, and its down side 1 kilometer deeper. There is a discrepancy consisting of a positive bump at the onset of the negative slope which is considered to be due to the additive effects of two regional positives, one to the north, and the other to the southeast of the line. The two positive anomalies are expected to counteract the more gradual slope which would be expected for a fault at this depth, producing a positive discrepancy.

Essentially all the information of short wavelength nature is

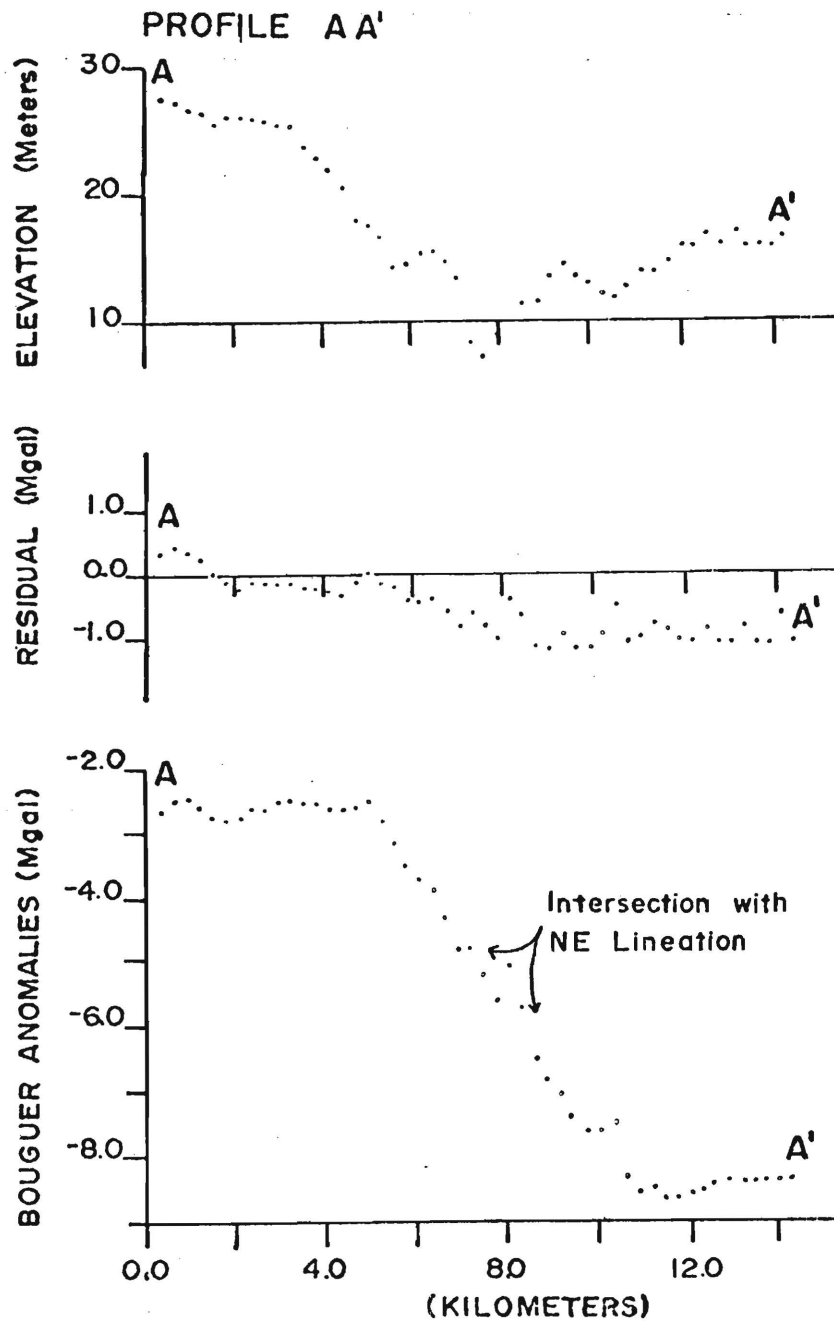

Figure 14. Composite Profile AA'. (The negative gradient is coincident with N.E. linear anomaly and both the residual gravity and Bouguer gravity are paralleled to some extent by the topography.)

contained in the residual profile. The slight negative trend to the east may be indicative of a thickening of the low density zone. The more positive portions of the residual may indicate the biasing effects of the two regional positives.

The cross correlation coefficients determined for this profile show strong positive relationships between elevation and both gravity and residual gravity profiles. Comparison of the elevation profiles with the gravity profiles shows the elevation to have a more gradual negative slope to the southeast than that of the gravity. This gradual slope in the elevation may show the type of response which would be expected at the surface of a blanket of unconsolidated sediments if basement faulting took place. The strong correlation between the residual profile and elevation possibly shows the extension of the faulting into consolidated beds above the basement which could be evidence for recent faulting along the northeast lineation. A similar effect would be expected for differential compaction.

#### Profile BB'

Detailed gravity profile BB' is similar in shape to profile AA'. The steep negative gradient of profile BB' is -0.7 milligal per kilometer and is coincident with the residual northeast lineation (Figure 15). Comparison of this profile with the theoretical "simple fault" model curves shows that the best fit to the observed profile is a fault with its upthrown side 1 kilometer deep and its downthrown side 2 kilometers deeper. While the "noisy" nature of this profile makes accurate throw determination difficult, the curvature of the profile is still best fit by a 1.5 kilometer throw which is interpolated from

Figure 15. Composite Profile BB'. (The negative Bouguer gradient is coincident with N.E. linear anomaly and the Bouguer gravity is paralleled to some extent to the topography.)

the curves for faults having 1 and 2 kilometer throws at a depth of 1 kilometer (Figure 16).

The residual profile shows the noisy character of the actual profile. There is a slight negative gradient indicative of thickening sediments to the southeast, but the noise in the residual makes interpretation of structure difficult.

Cross correlation coefficients determined for this profile show a strong positive correlation between the gravity and the topography. Examination of the elevation change with respect to the gravity shows the elevation to begin to drop prior to the corresponding decrease in the gravity profile. This may show surface response to previous faulting. No such correlation is seen between the residual profiles and topography. Lack of such correlation may indicate that there is no fault extension into the consolidated beds above the basement. It should be noted that the resolution depth for the residual profiles is strongly related to the nature of the surrounding regional field. For example, if the regional field is constant, then undulations upon that field are essentially nondistorted in the residual. However, if the regional gravity field changes rapidly, the shape of the short wavelength anomalies produced by near surface structures are distorted in the residual. This may be the case along this profile. However, it suffices to say that the residual gives no evidence for fault extension into the sedimentary layers above the basement, but that this lack of evidence is not conclusive.

#### Profile CC'

Detailed gravity profile CC' shows the effect of three regional

Figure 16. Comparison of the Shape of the Normalized Bouguer Gravity Profiles AA' and BB' with Shape of the Normalized Anomalies Calculated from "Step" Fault Models.

features. The southeastern end of the profile shows the cumulative effects of the southern negative anomalous zone and the central positive anomalous nose-like feature. The anomalies observed across the "nose" have a flat character. As the profile crosses the northeast lineation, a slight dip is observed prior to the increase in the gravity field due to the edge of the west central positive (Figure 17).

Since the profile is not perpendicular to the isogals throughout its traverse, no attempt was made to obtain depth information. However, it is interesting that the northeast lineation intersects this profile coincident with the slight dip. Qualitatively, such a dip in the profile would be expected if the two features producing the positive anomalies were at different depths. The magnitude and width of the regional nose-like positive anomaly may indicate that it is deeper in the crust than the western central positive. Therefore, the dip may indeed represent an offset in the basement whose strike is northeast.

The residual profile is reasonably flat. There are short wavelength anomalies of low amplitude which oscillate about the 0.0 milligal line. Little structural information is contained in this profile.

The correlation coefficients for profile CC' show a positive relationship between actual gravity and topography. Observation of the elevation profile shows the elevation to drop off just prior to the slight dip in the gravity profile. Profile CC', as did AA' and BB', may imply that the basement structure is paralleled by the topography. The coefficient computed for the residual profile and elevation is weakly positive.

Figure 17. Composite Profile CC'. (This detailed gravity profile shows a slight depression in the gravity anomalies located at the intersection of the profile and the N.E. linear anomaly.)

### Profile DD'

Detailed gravity profile DD' is 44 kilometers in length. The length of this traverse, as well as the widely varying regional field along the profile, makes discussion of this profile more informative if done in three sections. The sections are marked on the profile and are referred to as the northwest, central, and the southeastern sections (Figure 18).

The northwestern section of this profile, aa', traverses the northwestern edge of the west central positive. The section does not cross the peak of the regional positive anomaly, nor is the traverse normal to the isogals. This results in distortion of the apparent anomaly with respect to its width and magnitude. Therefore, reasonable depth determinations are not easily obtained. Examination of the relationship between gravity and topography along this profile showed a strongly negative correlation. This negative correlation is also shared to some extent by the residual gravity profile.

The central section of profile DD', bb', shows a similar dip to that observed in profile CC'. This dip again corresponds to the northeastern lineation observed in the two-dimensional residual. The residual profile for this section also exhibits this slight dip. The elevation profile shows a gentle negative slope to the southeast which, to some extent, is paralleled by the gravity. This correlation is not nearly as positive as observed in the previously discussed profiles. The residual profile also parallels this decrease in gravity and elevation. Apparently, the correlation between gravity and elevation weakly suggests the presence of basement offset as well as the extension

Figure 18. Composite Profile DD'--Sections aa' and bb'. (Section bb' of the gravity profile shows a slight depression in the Bouguer anomalies associated with the N.E. linear anomaly.)

of this offset into the lower density region above the basement.

The southeastern section of profile DD', cc', shows both the residual gravity and the observed gravity to decrease in response to the southern basin. The traverse of this section is essentially perpendicular to the regional isogals and is used to obtain a depth to the nose-like positive feature (Figure 19). The effects of the gravity field of the surrounding high and low density regions may distort the gravity anomaly in such a manner as to bias the minimum depth upward. Using the empirical formula for depth to a buried horizontal cylinder, the minimum depth to the center of the body is determined to be 4.2 kilometers. The effective radius of the cylinder is found to be 2.1 kilometers for a density contrast of  $0.3 \text{ gm/cm}^3$ . The estimated depth to the top of the nose-like positive is therefore approximately 2.0 kilometers.

#### Profile EE'

Detailed gravity profile EE' traverses the regional isogals considerably off normal. The profile crosses the northeast lineation, but does not show the pronounced depression or "simple fault" anomaly observed in the other profiles. This is not thought to indicate that the suspected offset truncates north of this profile, but that it is the result of the location and direction of the traverse (Figure 20).

Study of the profile with respect to the northeast lineation shows a slight change in positive gradient near the intersection. The residual profile shows a sharp change from positive to negative anomalies at this location. This may indicate that the area south of the western central positive is of lower density. The profile traverses the edge of the nose-like appendage, producing the positive

Figure 19. Composite Profile DD'--Section cc'. (Section cc' traverses the nose-like positive anomaly. Using the empirical formula for depth to a buried horizontal cylinder, a depth of 2.8 kilometers is computed for the coastal feature which produces the observed gravity anomaly.)

Figure 20. Composite Profile EE'. (The profile shows change in gravity gradient associated with N.E. linear anomaly.)

residual anomaly, and then enters the lower density region. If this sudden change in density contrast is caused by faulting, the direction of fault motion is difficult to determine unless offset of the higher density rock about the lineation is established.

Cross correlation coefficients obtained for this traverse indicate a strong positive relationship between gravity and topography. The relationship between the residual gravity and topography is weakly positive. The elevation profile shows that the elevation rises suddenly in the southeast and decreases gradually to the northwest. The sudden elevation change does not appear to be related to the northeast lineation. As the profile progresses out of the southeastern flood plain of the Edisto River, the topography rises. The decrease in elevation to the northwest is also thought to be related to the Stono River valley. Therefore, this profile is considered to give little evidence for basement control of surface topography, but may instead indicate a poor choice of reduction density.

#### Profile FF'

Detailed gravity profile FF' crosses the most northeastern positive as well as the northeastern lower density region modeled as part of the vertically down-faulted region in profile AA' (Figure 21).

The empirical formula for depth to a buried horizontal cylinder was applied to the northeastern positive. The depth to the top of the body, based on a  $0.3 \text{ gm/cm}^3$  density contrast, was determined to be 1.2 kilometers. The effects of the positive anomalies on either side of the basin made depth determinations difficult, and the basin depth calculated using a cylinder density of  $-0.2 \text{ gm/cm}^3$  does not agree with

Figure 21. Composite Profile FF'. (The profile is modeled by two cylinders to obtain depth estimates for the crustal features which produce the observed gravity anomalies.)

the depths of 2 to 3 kilometers estimated by profiles AA' and BB'.

The correlation coefficients between elevation and gravity computed for this profile were weakly negative. Examination of the elevation with respect to residual and actual gravity shows that the elevation rises from north to south. There was a sudden increase in elevation near the beginning of the gravity low. This slight negative correlation may indicate that terrain corrections are necessary for sections of this profile. The variations in the elevation could produce terrain effects on the order of 0.25 milligal.

#### Profile GG'

Detailed gravity profile GG' is 38 kilometers long and traverses somewhat parallel to the northeastern linear anomaly (Figure 22). In the northeastern quadrant of the Summerville gravity map, the profile traverses a small feature which was observed as a small positive anomaly in the low density sedimentary region. The residual profile shows this peak more clearly than the observed gravity profile. The empirical formula for depth to a buried horizontal cylinder was used to approximate the anomaly. The center of the body was computed to be 1.6 kilometers beneath the surface. A density contrast of  $0.3 \text{ gm/cm}^3$  was used to determine the effectiveness radius of 0.5 kilometers. The top of the feature was determined to be approximately 1.0 kilometers beneath the surface. The continuation of the profile to the southwest distorts the western central anomaly because the profile crosses the anomaly at a  $45^\circ$  angle with respect to normal.

The correlation coefficients between elevation and gravity for this profile are strongly negative. The surface feature thought to have

Figure 22. Composite Profile GG'. (This detailed gravity profile parallels to some extent the N.E. linear anomaly.)

produced this effect is the Edisto River channel, which crosses the western central gravity positive. There could be a structural reason for this. Differential weathering on the Pre-Cretaceous surface of the unstable high density material which is now at a depth of 2500 feet may be related to the entrenchment of the river. However, this hypothesis is not well supported by the data.

#### Profile HH'

Detailed gravity profile HH' shows one broad peak resulting from the orientation of the traverse with respect to the isogals. This distortion curtails the information which can be obtained concerning depth and shape. The southern end of this profile traverses the northeastern lineation. At this location there is very little evidence observed for the continuation of this trend southward. Traverse HH' crosses the northeastern trend near the intersection of the intersection of the northeastern lineation and profile EE'. Profile EE' did not strongly suggest the presence of faulting either. This may indicate that the hypothesized fault trace terminates, or changes direction, north of these profiles. The direction change is considered to be the more likely because the southern low density zone appears similar to the northeastern basin (Figure 23).

The coefficients computed between the elevation and gravity for profile HH' are negative. As seen in profile GG', the positive gravity anomaly was in a region of lower elevation.

#### Profiles II', JJ', and KK'

Detailed gravity profiles II', JJ', and KK' are not considered to give valuable structural information and will not be described.

Figure 23. Composite Profile HH'. (The topographic profile suggests that areas of lowest elevation are associated with positive gravity anomalies.)

However, the locations and plots of the observed gravity along the profiles are given for completeness of text (Figures 24 and 25).

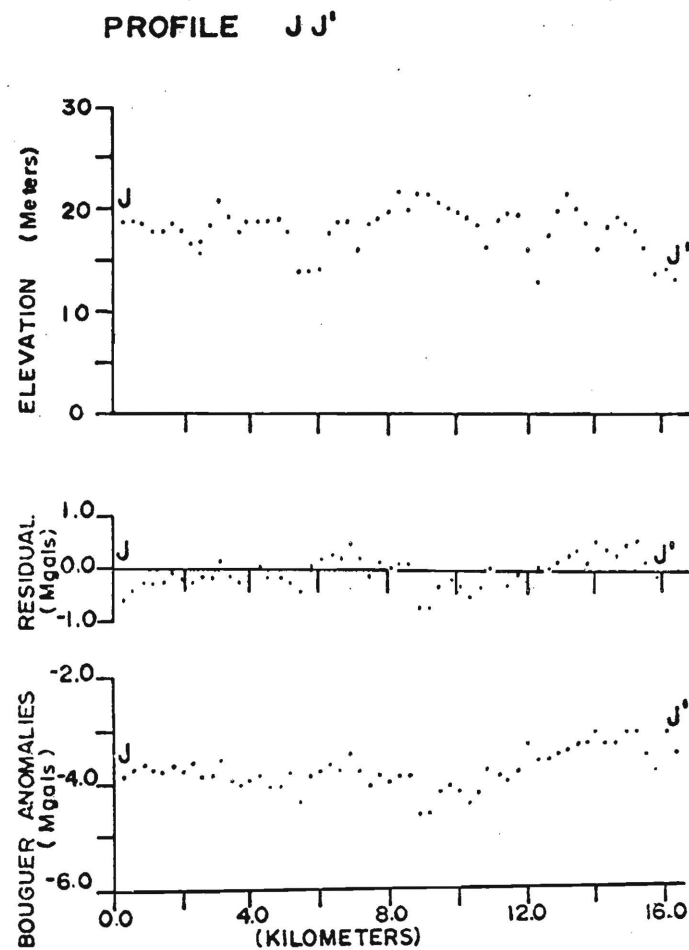

Figure 24. Composite Profiles II' and JJ'.

## CHAPTER VI

## DISCUSSION AND CONCLUSIONS

Examination of the Charleston-Summerville, South Carolina, epicentral zone by detailed analysis of gravity reveals probable existence of a linear alignment of gravity anomalies oriented N 40° E. This lineation is observed in the simple Bouguer gravity map as a feature defined by the western termination of the northeastern and southern negative gravity anomalies, which imply low density crustal rocks. The lineation intersects the positive gravity anomalies in a region where the isogals spread to form a nose-like positive anomaly protruding to the east. This northeastern alignment of anomalies is observed as a linear zone of negative anomalies in the two-dimensional residual gravity map and as a strong trend in the two-dimensional spectral analysis of the residual gravity map.

Three-dimensional modeling of this linear feature in the Summerville area supports the interpretation of this feature as a vertical fault having an offset of 1 to 2 kilometers. The central high density regions in the first gravity model are interpreted to be basic plugs of density  $2.9 \text{ gm/cm}^3$ . The surrounding  $2.8 \text{ gm/cm}^3$  material is considered to be basic flows. These flows appear to have been down-faulted to the east about the northeast lineation. Thus, the nose-like appendage modeled at a depth of 4.5 kilometers, having a thickness of 4 kilometers, is interpreted to have once been at a depth of 2.5 kilometers. The low density zones to the northeast and southeast are considered to

be sedimentary basins containing beds of average density  $2.4 \text{ gm/cm}^3$ . These low density zones appear to be associated with this northeastern lineation. Assuming this lineation is representative of a fault, the down-faulted flows, as well as the sedimentary basins, may be elements of a graben. The second three-dimensional model also supports this vertical offset.

The three-dimensional models do not extend upward to the depth of known crystalline basic basement rock. However, both theoretical models indicate faulting along the northeast lineation. Distortions in the depth and shape of structural bodies are difficult to avoid in gravity models. Differences in depth of two bodies of similar densities are more reliable. Peter Popanoe of the United States Geological Survey (personal communication) found the density of the basaltic basement rock to be  $2.72 \text{ gm/cm}^3$  at a depth of 2800 feet. This density is nearly the same as the Bouguer reduction density, and would not produce a Bouguer anomaly. The depth at which both these models predict dense basalts may be more reasonable.

On the basis of two-dimensional theoretical curves for a simple fault, two detailed gravity profiles (AA' and BB') which cross this lineation, show a fault which has a depth of 1 kilometer and a throw of 1 to 2 kilometers to best fit the observed profiles. This throw is supported by the determination of the depth to the top of the nose-like positive in profile DD'.

Four of the five gravity profiles which traverse the suspected fault suggest a strong direct relationship between the gravity and topography. Examination of the elevation profiles suggest that basement

faulting may control the surface topography. In general, this relationship only appears to be true if the density contrast of basement rock remains similar in sign throughout the traverse. In profiles which cross both low density and high density rock, the correlation functions show an inverse relationship between gravity and topography. Again, this may suggest basement control of topography. Positive gravity anomalies are generally found in regions of low elevations. This may indicate that the differential weathering of unstable basic basement rock was more rapid than the surrounding sedimentary sequences, producing small basement valleys which contribute to the channeling of the rivers from the Cretaceous to the present.

The residual gravity map, as well as the gravity profiles, suggests that the northeast lineation truncates near the northern edge of the northeastern basin. The southwestern extent of this suspected fault is not as obvious. It is possible that this fault is related to the southern basin and therefore extends out of the area of investigation. It is also possible that the northeastern and southern basins are the same basins (S.C. Gravity Map, in preparation).

It is not unreasonable to expect to find such a graben fault in the Coastal Plain basement. Sheridan (1974) predicted such major grabens might result from Protoatlantic continental rifting. Mayhew (1974) suggested that volcanics were common in the rift zones and were concentrated in the outer part or the outer shelf, adjacent to the locus of continental breaching. The amplitude of the throw on such a fault is also reasonable and is comparable to that of the Deep River Basin in North Carolina (Reinemund 1955). Such a down-faulted block also has

tectonic implications. Isostatic readjustment of such a block could reactivate old faults or create new ones within the graben. The November 22, 1974, event was located near this northeast lineation within the proposed graben (Tarr, personal communication). The depth of the event was calculated to be approximately 10 kilometers, which is near the base of the down-faulted basic material in the graben observed in three-dimensional Model No. 1.

Gravity analysis does not, of course, yield unique solutions. Justification of the presence of faults such as that postulated here, would require additional geophysical study. Seismic reflection studies, as well as more detailed well loggings, are the logical tools for the determination of the validity of such an offset in the basement surface. It is hoped that these methods will be applied and that the cause of the earthquake activity in the Charleston area will soon be determined.

## APPENDIX I

## GRAVITY DATA AND DATA REDUCTION

Gravity measurements were obtained and reduced by standard techniques. The data consists of approximately 2000 measurements, 1000 of which are observations along 11 detailed gravity profiles. The location of these profiles are described in Table 2. The remaining 1000 measurements are regional data having an average station spacing of 1 kilometer.

Thr gravimeters used in this study were both of Lacosta-Romberg design. The meters were loaned to this project by Peter Popenoe of the United States Geological Survey and Dr. Al Erickson of the University of Georgia. Both meters, when read by a single operator, have a reading precision of  $\pm 0.02$  milligal. Instrumental drift over an eight-hour period is typically 0.15 milligal, but may be as high as 0.4 milligal for the same period. Both meters have internal temperature controls and are maintained at a constant temperature of  $49^{\circ}\text{C}$  to eliminate mechanical drift due to temperature change. The uncertainties in drift and reading precision combine to give a total measurement precision of  $\pm 0.15$  milligal.

Five new gravity base stations were established from the state base of Branchville, South Carolina. These base stations were established at either benchmarks or controlled intersections and were used to correct for drift during surveys. Information concerning the location and value of these bases is given in Table 3.

Observed survey drifts are listed in Table 4.

The effect of latitude on gravity measurements was compensated for by using the international gravity formula of 1931 (Dobrin, 1960, p. 187). Drift corrections for each of the surveys were made by assuming linear drift between base station readings after removal of tidal effects. The data were reduced using the standard Bouguer reduction density of  $2.67 \text{ gm/cm}^3$ .

The data, in standard Department of Defense computer and format, are listed in Table 5 (Figure 26).

Eight 7.5 minute topography maps and two 15' topographic sheets were used for location control and some elevation control. The 7.5 minute United States Geological Survey maps were Summerville (1971), Mt. Holly (1971), Stallville (1971), Ladson (1971), Johns Island (1971), Ravenel (1971), Legerville (1971), and Wadmalaw (1971). The two 15' quadrangles were Cottageville (1943) and Ridgeville (1943). Elevations of regional stations' locations were determined by interpolation between topographic contours and are estimated to be  $\pm 3$  feet on the 7.5 minute sheets and  $\pm 5$  feet on the 15' quadrangles. It is important to note that in some areas, the topography has been altered since the 15' quadrangles were published. Due to rapidly varying barometric conditions in the coastal regions, the barometric altimeter proved less than satisfactory. Profile measurements in most instances were obtained by recording elevation differences obtained by level sighting. The accuracy of these elevations is estimated to be  $\pm 1$  foot. The estimated uncertainty in the regional gravity due to elevation is  $\pm 0.15$  milligal, but may be as high at  $\pm 0.3$  milligal. The uncertainty of profile measurements due to elevation is estimated to be  $\pm 0.05$  milligal. The total maximum

uncertainty of the regional data obtained by combining the measurement precision and the uncertainty due to elevation control is estimated to be  $\pm 0.20$  milligal. The maximum estimated uncertainty of the profile data is  $\pm 0.15$  milligal.

Table 2. Description of Profile Location

Profile Designation	Profile Location
AA'	The profile is established along U.S. Highway 176. It begins at the intersection of U.S. Highway 176 and Berkeley County Road 276, and ends at the intersection of U.S. Highway 176 and Berkeley County Road 45.
BB'	The profile is established along U.S. Highway 78 and Berkeley County Road 29. It begins on U.S. Highway 78 at Jedburg, South Carolina, and continues along U.S. Highway which changes to Berkeley County Road 29. The profile ends at the intersection of Berkeley County Roads 29 and 136.
CC'	The profile is established along South Carolina Highway 642. It begins at the intersection of South Carolina Highway 642 and U.S. Highway 12A, and ends at the intersection of South Carolina Highway 642 and South Carolina Highway 62 just outside Charleston, South Carolina.
DD'	The profile is established along Colleton County Road 30 and South Carolina Highway 61. It begins at the intersection of Colleton County Road 30 and Colleton County Road 19 and continues along County Road 30 to the intersection with South Carolina Highway 61. The profile ends along South Carolina Highway 61 approximately 1.5 km southeast of its intersection with South Carolina Highway 7.
EE'	The profile is established along the Old Dorchester-Charleston County Line Road. It begins at the intersection of County Line Road and U.S. Highway 17, and ends at the intersection of County Line Road and South Carolina Highway 38.
FF'	The profile is established along old U.S. Highway 52. It begins at the intersection of U.S. Highway 52 and Berkeley Road 50, and ends at the intersection of U.S. Highway 52 and the Charleston Municipal Airport Road.
GG'	The profile is established along U.S. Highway 17-A beginning at the intersection of Berkeley Road 50 and U.S. Highway 17-A, and ends at the U.S. 17-A Edisto River bridge.

Table 2. Continued

Profile Designation	Profile Location
HH'	The profile is established along South Carolina Highway 165. It begins at the intersection of South Carolina Highway 165 and U.S. Highway 17-A, and ends at the intersection of South Carolina Highway 165 and U.S. Highway 17.
II'	The profile is established along South Carolina Highway 27. It begins along Highway 27 at Ridgeville, South Carolina, and ends at the intersection of South Carolina Highway 27 and South Carolina Highway 61.
JJ'	The profile is established along Dorchester County Road 58. It begins at the intersection of County Road 58 and Dorchester County Road 22, and ends along Berkeley County Road 22, a continuation of Dorchester County Road 58, 2.4 km north of New Hope Church.
KK'	The profile is established along Berkeley County Road 275. It begins at the intersection of County Road 275 and U.S. 17-A, and ends at the intersection of County Road 275 and U.S. Highway 176.

Table 3. Base Stations Used and Established

Name of Station	Description of Station	Location		Elevation (Feet)	Value (Total)
		Long.	Lat.		
Branchville, S. C.	Established by AMS-(1929) at Railroad station at BM "M25 1934 126.630"	80° 49.0' W	33° 150' N	126.601	979590.786
*Lotts Corner S.C. Base	Controlled intersection--Summerville Quad	80° 14.96 W	33° 3.25 N	62.	979574.383
*17-A Base	Established at BM on U.S. 17-A in yard of Mrs. Williams, Mt. Holly Quad	80° 7.17' W	33° 2.60 N	81.	979576.627
*642 Base	Established at BM on S.C. 642, 28 mile S.E. of intersection of S.C. 642 & 165. BM is on telephone pole. Stallsville Quad	80° 11.82' W	32° 57.97' N	48.	979574.077
*Ashley Phosphate Base	Established at controlled intersection in Ashley Heights .26 N.E. of railroad crossing in front of a Quick Shoppe on Ashley Phosphate Rd.	80° 3.06' W	32° 55.9' N	29.	979567.485
*U.S. 61 Base	Established at controlled intersection on U.S. 61, .2 mile S.E. of railroad crossing at Springfield Estates. The base is in front of a Quick Shoppe	80° 3.20' W	32° 50.37' N	16.	979560.659

\*Base stations which were established in this study.

Table 4. Survey Drift

Georgia Tech Survey Number	Station Numbers	Drift (Mgals/hr)	Time Between Base Stations

## APPENDIX II

## COMPUTER PROGRAMS FOR GRAVITY

## ANALYSIS AND MODELING

A computer program was developed for the calculation of the two-dimensional residual gravity data using a smoothing function defined by Shapiro (1970). A listing of the subroutines necessary for calculation of the regional gridded data, as well as line printer plotting of the data in grid form, is given in Table 6.

A computer program was developed for computation of the Fast Fourier transformation of the residual data to allow for lineation analysis. The necessary subroutines for the spectral calculations are given in Table 7.

A third computer program was developed for the calculation of vertical gravity anomalies of arbitrarily shaped three-dimensional structures using the procedure outlined by Talwani, et al., (1960). This program, including the subroutines necessary for line printer plotting, is given in Table 8.

A fourth computer program was developed by George H. Rothe, III (1973) for the computation of vertical gravity anomalies caused by two-dimensional structure. Rothe used the method of Talwani, et al., (1959) for this computation. A copy of this program, including the necessary subroutines for lone printer plotting, is given in his thesis.
